ABSTRACT

The 'Diffuse Ionized Medium' (DIM) comprises a significant fraction of the mass and ionization requirements of the ISM of the Milky Way and is now known to be an energetically significant component in most normal star-forming galaxies. Observations of the ionized gas in starburst galaxies have revealed the presence of gas with striking similarities to the DIM in normal galaxies: relatively low-surface-brightness and strong emission from low-ionization forbidden lines like [SII]$\lambda\lambda$6716,6731. In this paper we analyze Hα images and long-slit spectra of samples of normal and starburst galaxies to better understand the nature of this diffuse, low-surface-brightness gas. We find that in both samples there is a strong inverse correlation between the Hα surface-brightness ($\Sigma_{H\alpha}$) and the [SII]/Hα line ratio at a given location in the galaxy. However, the correlation for the starbursts is offset brightward by an order-of-magnitude in Hα surface-brightness at a given line ratio. In contrast,

we find that all the galaxies (starburst and normal alike) define a *universal* relation between line ratio and the *relative* Hα surface brightness ($\Sigma_{H\alpha}/\Sigma_e$, where Σ_e is the mean Hα surface brightness within the galaxy half-light radius). We show that such a universal correlation is a natural outcome of a model in which the DIM is photoionized gas that has a characteristic thermal pressure (P) that is proportional to the mean rate of star-formation per unit area in the galaxy (Σ_{SFR}). Good quantitative agreement with the data follows if we require the constant of proportionality to be consistent with the values of P and Σ_{SFR} in the local disk of the Milky Way. Such a scaling between P and Σ_{SFR} may arise either because feedback from massive stars heats the ISM or because Σ_{SFR} is determined (or limited) by the mean gas pressure.

1. INTRODUCTION

The 'Diffuse Ionized Medium' (DIM) is recognized as an important component of the ISM in galaxies. This gas, first discovered as the 'Reynolds Layer' in our Galaxy (see, e.g. Reynolds 1990 for a review), seems to be ubiquitous in late-type spiral (e.g. Hoopes et al. 1996; Wang, Heckman & Lehnert 1997–hereafter WHL) and irregular galaxies (e.g. Martin 1997). Indeed, the universal existence of the DIM has been inferred from integrated emission-line ratios of a large sample of normal late-type galaxies (Lehnert & Heckman 1994). The observed properties of the DIM are characterized by relatively strong low ionization forbidden lines compared to normal HII regions, a low surface brightness, a rough spatial correlation with HII regions, and a significant contribution ($\sim$20%–40%) to the global Hα luminosity.

The observations raise many interesting questions about the physical and dynamical state of the DIM that are still to be answered. The energy required to power the DIM suggests that the gas either soaks up nearly 100% of the mechanical energy supplied by supernovae and stellar winds, or the topology of the interstellar medium must allow roughly 1/3 of the ionizing radiation produced by massive stars to escape HII regions and propagate into the disk. Although the diffuse nature of the DIM suggests that it maintains pressure balance with the rest of the ISM, little observational evidence has been collected to support this idea. Only in the Reynolds layer has the electron density been derived through observations of pulsar dispersion measures (e.g. Reynolds 1993) and seems consistent with

the typical ISM thermal pressure of ∼3000 K cm^{-3} (Jenkins et al. 1983). Furthermore, it is still unknown how or if this pressure is regulated by the hotter coronal-phase gas created by supernovae.

While these questions wait to be answered, a study of the general properties of the DIM in galaxies with widely differing star formation rates (SFRs) per unit area or per unit volume might provide us with more clues in this endeavor. The simple reason behind this is that star formation has a significant impact on the ISM. The energetics and dynamics of the DIM must therefore be strongly influenced (or even regulated) by the feedback from star formation (e.g. Elmegreen & Parravano 1994). In starbursts, for example, the intense star formation can provide feedback to the ISM that might be significantly different *qualitatively* from the case in quiescent galaxies. Dynamically, the collective effect of supernovae exploding in a hot rarefied medium created by previous supernovae may minimize radiative losses and thus provide the energy to drive a galactic scale outflow in starbursts (e.g. Heckman, Armus & Miley 1990). Thus, we would expect a more significant kinematic disturbance in the DIM in starbursts than in normal disks and a greater role of shock-heating in the energetics throughout the ISM. That is, the hot coronal-phase gas in starbursts should be more pervasive than in normal disks (as parameterized by the *porosity*, McKee & Ostriker 1977) and would therefore have the potential to regulate the pressure of the ISM over a relatively larger volume. Since the DIM traces the heating and ionization of gas occupying a substantial fraction of the volume of the ISM and comprising much of its mass, the above issues are closely tied to our understanding of the DIM.

We note that among the galaxies that have been searched for a DIM, most are normal spirals and irregulars. However, observational data suggest that there is a similar DIM component in starburst galaxies. For instance, in the nearby starburst NGC 253, Hoopes et al. (1996) found a faint Hα-emitting gas surrounding bright HII regions that is similar to the DIM in other quiescent spirals. More generally, the spectra of extra-nuclear regions of starbursts (e.g. Lehnert & Heckman 1995) show that the relative strengths of the low-ionization lines are high—very similar to what has been observed in the DIM in normal galaxies. It is therefore worthwhile to systematically study the faint emission-line gas in starbursts and compare this gas to the DIM in normal galaxies.

2. SAMPLE SELECTION AND DATA DESCRIPTION

In this paper we will explore the emission-line properties of galaxies with a wide range of star formation rates (SFRs) using long-slit spectroscopic data. Our sample includes both normal, quiescent late-type spirals and IR-selected starbursts. Our data on normal galaxies

come from a survey of the DIM in nearby face-on spirals. This subset involves seven galaxies selected on the basis of Hubble type (Sb and later), proximity (closer than 10 Mpc), large angular size (> 10 arcmin), and relatively face-on orientation (inclination < 65 degrees). Part of the data has been presented in Wang et al. (1997), and the rest can be found in Wang (1998). The reader can refer to these references for details of the observations and data reduction. Complete observational information is summarized in Table 1.

The starbursts are a sample of infrared-bright ($S_{60\mu m} > 5.4$ Jy), edge-on (a/b $\gtrsim 2$), infrared-warm ($S_{60\mu m}/S_{100\mu m} > 0.4$) galaxies compiled by Lehnert (1993, dissertation, Johns Hopkins University) and also described by Lehnert and Heckman (1995). Analysis of both samples of data can help us understand the physical state and dynamics of the ionized gas over a wide range of star formation rates.

We note that due to different sample selection criteria, the starbursts are generally much more distant and more inclined than our normal spirals. Otherwise, the major difference between the starbursts and the normal spirals is just the much larger star-formation rates per unit area (Σ_{SFR}) in the former (Lehnert & Heckman 1996b).

In order to compare our normal galaxies and starbursts, we used three quantities that have been measured with long-slit spectroscopy at many locations within each galaxy for both groups of galaxies. These are the line ratios represented by [SII]$\lambda\lambda$6716,6731/Hα, the Hα surface brightnesses, and the Hα or [NII]λ6584 linewidths. The [SII] doublet was selected to represent low ionization lines rather than [NII] because Nitrogen has a secondary nucleosynthetic origin, while Sulfur has a primary one. That is, the S/O ratio is independent of metallicity, while N/O $\propto$ metallicity (cf. Vila-Costas & Edmunds 1993). As shown by WHL this results in systematic differences in the [NII]/Hα ratio in the DIM in galaxies of different metallicity - differences that are not present in the [SII]/Hα ratio.

For our normal galaxies, we have multiple slit positions that spectroscopically sample representative regions in the disks of these galaxies (WHL; Wang 1998). We find that the emission-line properties in these galaxies vary spatially in a smooth way from the centers of HII regions out into the surrounding DIM.

Data for the starbursts are in the form of long-slit spectra centered on the nuclei and oriented along both the minor and major axes. The spectra have been extracted using 3 pixel spacing starting from the nuclei and moving outward along the slit. We can then examine the variations in starbursts from bright starburst cores to fainter surrounding nebulae, by analogy with our analysis of the normal galaxies. The starbursts are generally much more distant than our normal spirals. Therefore we sample the gas in starbursts on a much larger scale, as each spatial resolution element would encompass a large number of

HII regions.

The [NII]λ6584 linewidth is used to represent kinematics in starbursts, while either Hα linewidth (if EQW(Hα) $> 3\mathring{A}$) or [NII] linewidth (if EQW(Hα) $< 3\mathring{A}$) is used (see WHL) for our normal galaxy sample. This difference in the adopted linewidth is unlikely to affect our analysis significantly since the Hα and [NII] linewidths correlate well with one another for the starburst (Lehnert & Heckman 1995) sample.

The number of galaxies we can use in the starburst sample is limited by the availability of photometric data and other relevant information. We use 32 galaxies from this sample that have been observed spectroscopically under nearly photometric conditions and hence can provide us with line ratios, Hα surface brightnesses, and linewidths. We have excluded from this analysis the Circinus galaxy, whose Hα image in Lehnert & Heckman (1995) is dominated by the central AGN and NGC 5253, which is a dwarf galaxy unlike the members of our normal galaxy sample.

In the following analysis we will attempt to normalize the star-formation rate in a given location of a galaxy by dividing the measured Hα surface brightness at that location by the average Hα surface brightness in the galaxy. To do so, we define a galaxy effective Hα surface brightness Σ_e as the ratio of half of the total Hα flux to the solid angle subtended by the area within the Hα half-light radius(πr_e^2). This is effectively the average surface brightness within the Hα half-light radius. In order to do this scaling we further selected 19 objects out of the subsample of 32 galaxies for which Lehnert and Heckman (1995) have measured the Hα half-light radii and total Hα fluxes. The measured total Hα+[NII] flux is corrected to the Hα flux based on the measured [NII]/Hα ratio within $2r_e$. Thus, Σ_e can be estimated for these 19 starburst galaxies and used to scale the observed values of $\Sigma_{H\alpha}$ as measured at different positions in each galaxy.

All the spectral data in the normal spiral subsample have been properly calibrated for absolute surface brightness. In addition, we have measured r_e from the Hα images (WHL and Wang et al. 1998 in preparation). Therefore all data from this subsample can be utilized in this analysis.

We have not attempted to correct the observed Hα surface brightnesses for the effects of internal reddening. This is likely to be significant. For example, Kennicutt (1983) estimates an Hα extinction of about 1 magnitude for typical giant HII regions in normal galaxies, and Armus et al (1989) find a typical value of about 2 magnitudes for IR-selected galaxies. Note that while an extinction-correction would increase the absolute values of the Hα surface brightnesses (and implied star-formation rates per unit area) it will only affect the normalized surface-brightnesses defined above if the extinction varies spatially.

We return to these issues later in the paper.

3. RESULTS

The relative strengths of the low-ionization emission-lines in starbursts correlate well with Hα surface brightness (Figure 1). Data for HII regions and the DIM in our normal galaxies are also plotted for comparison. Both sets of data show higher strengths of low-ionization lines at lower surface brightness, and they all suggest a strong continuity in physical state between the high surface brightness and low surface brightness gas. In fact, the correlations can be roughly described as a power-law relation between [SII]/Hα and $\Sigma_{H\alpha}$ with similar slopes for both samples. However, there is a noticeable offset between the two groups of galaxies: at a given line-ratio, the gas in the starbursts has an average surface brightness that is about an order-of-magnitude higher than the gas in the normal galaxies. This is not surprising as the starbursts have much higher Hα surface brightnesses in general, and correspondingly higher Σ_{SFR}. We will further examine this systematic difference in surface brightness in the following paragraphs. We reject some DIM data points near the nucleus of M 81 due to heating processes other than pure photoionization by young stars in that region (cf. Devereux, Jacoby, & Ciardullo 1995, 1996).

While the line-ratios correlate strongly with surface-brightness, the starburst sample shows no correlation between linewidth and $\Sigma_{H\alpha}$, and only a weak correlation between linewidth and [SII]/Hα. Linewidths of the gas in starbursts are typically a few hundred kilometers per second, about a factor of 10 larger than those in normal galaxies. The data for the normal galaxies bear little resemblance to that of the starbursts with respect to these kinematic relations. It is likely that kinematics of the emission-line gas are different in the two types of galaxies for two major reasons. For the distant highly-inclined starbursts, the spectra sample a large number of emission line nebulae across starburst disks even within a small aperture, and the lines may be broadened by relative motions among the nebulae. Supernova-driven superwinds are also responsible for much of the linewidth broadening (Lehnert and Heckman 1996a), especially along the minor axis. Thus we conclude that linewidths do not track well with other emission-line parameters for the combined galaxy sample.

In starbursts the continuity between high surface brightness regions (starburst nuclei) and low surface brightness (outer) regions, together with the lack of correlation between kinematics and emission line intensity ratios, suggests that the gas is mainly photoionized instead of mechanically heated. While we have drawn the same conclusion for the gas in the normal galaxies (WHL), Figure 1 shows a more general trend that is applicable to

the gas in starbursts as well. It is not surprising that most of line emission results from photoionization since the ionizing radiation energy from OB stars is about an order of magnitude higher than the total kinetic energy released by supernovae and stellar winds (cf. Leitherer & Heckman 1995).

To further explore the possibility of photoionization, we need to understand the Hα surface brightness offset between the two groups of galaxies in Figure 1, which is presumably physically related to the much higher star formation rates per unit area in the IR-selected starbursts. To test this idea, we adopt the effective surface brightness Σ_e defined in section 2 above to scale the observed values of $\Sigma_{H\alpha}$ and then plot the line-ratio [SII]/Hα versus relative (dimensionless) surface brightness $\Sigma_{H\alpha}/\Sigma_e$ (Figure 2). We have excluded the starburst data beyond $2r_e$ because those data are relatively noisy and are more likely affected by superwind-driven shock-heating processes in the galaxy halos (Lehnert & Heckman 1996a).

Figure 2 shows remarkably universal pattern of line-ratio variation as a function of *normalized* surface brightness. The scaling by Σ_e has successfully eliminated the systematic difference in surface brightness at a given line-ratio between the two groups of galaxies. Figure 2 demonstrates the interesting similarities in emission-line properties not only between HII regions in normal spirals and in starburst nuclei, but also between the DIM in normal galaxies and the relatively faint emission-line gas surrounding starburst nuclei. The universal continuity between high surface brightness and low surface brightness gas suggests that these emission-line properties all vary with a single parameter and therefore provides further support to the idea of photoionization as the dominant mechanism.

Because of the similarity in emission-line properties, we propose that the fainter emission-line gas in starbursts and the DIM in normal galaxies has the same physical nature. While it remains to be confirmed observationally that the low surface brightness gas in the starbursts is generically diffuse rather than from the sum of many faint, discrete HII regions, our conjecture is supported by Hα imaging results of the nearest starburst galaxies like M 82, NGC 253, NGC 5253, and NGC 1569 (cf. Lehnert & Heckman 1995, Marlowe et al 1995; Martin 1997). In addition, we (Wang 1998; Wang et al. 1998) have analyzed our Hα images of the normal galaxies and find that there is no *absolute* Hα surface brightness limit that cleanly separates the DIM from bright HII regions. Instead, we show that defining the DIM in terms of a normalized surface-brightness analogous to that described above leads to a natural segregation that is independent of a galaxy's mean surface brightness in Hα. This implies that even in a starburst galaxy a DIM component would exist, but this diffuse gas will have a characteristically high absolute surface brightness. Since the mean $\Sigma_{H\alpha}$ seems to be a reasonable dividing point between the DIM and HII regions, we suggest

that for the sample galaxies discussed in this paper, a crude surface brightness limit is the $\Sigma_{H\alpha}$ averaged within the half-light radius (=Σ_e). Therefore $\Sigma_{H\alpha}/\Sigma_e = 1.0$ could be used to isolate the 'DIM' gas in Figure 2.

For simplicity, in the following discussion we will tentatively adopt the same acronym DIM for the faint gas in the starbursts. We proceed to use a generic photoionization model to explain the correlation in Figure 2 and then address other implications of the data.

4. DISCUSSION

4.1. Photoionization of the DIM

The observed inverse correlation between the relative strength of the low-ionization lines and the Hα surface brightness could have a simple physical explanation if the emitting gas clouds all have roughly the same density. In this case, the higher the value of the local intensity of the ionizing radiation field, the higher the value of the ionization parameter U (defined to be the ratio of the densities of ionizing photons and electrons within a photoionized gas cloud). Simple ionization equilibrium arguments show that U determines the ionization state of the gas, while recombination means that the Hα surface brightness will be proportional to the intensity of the ionizing radiation field. Thus, the proportionality between U and the Hα surface brightness will naturally produce enhanced relative intensities of low-ionization lines in the faint gas (cf. Domgörgen & Mathis 1994).

The *generalized* relation between line-ratio and $\Sigma_{H\alpha}/\Sigma_e$ for the DIM in Figure 2 could then be explained *if* there is a direct proportionality between the average thermal pressure in the diffuse interstellar medium and the average star-formation rate per unit area in the galaxy. That is, the ratio of the Hα surface brightness at a particular location compared to the mean value in the galaxy would then be proportional to the local value of the intensity of the ionizing radiation field divided by a quantity that is proportional to the thermal pressure and hence the density of the photoionized cloud (T $\sim 10^4$ K). Thus, $\Sigma_{H\alpha}/\Sigma_e \propto U$.

Later in this section, we will briefly discuss some of the physics that might lead to such a proportionality. Here we simply remark that there is good empirical evidence that this proportionality is roughly obeyed when extreme starbursts like M 82 are compared to the disks of normal spirals like the Milky Way. In the M 82 starburst, the thermal gas pressure is $P/k \sim 10^7$ K cm^{-3} (Heckman, Armus, & Miley 1990) and the star-formation rate per unit area is $\Sigma_{SFR} \sim 30$ M$_\odot$ yr^{-1} kpc^{-2} for a Salpeter IMF extending from 0.1 to 100 M$_\odot$ (cf. Kennicutt 1998). Heckman, Armus, & Miley (1990) and Lehnert & Heckman (1996b) show these are typical values for both parameters in extreme starbursts. In comparison, in

the local Milky Way disk the thermal gas pressure is $P/k \sim 10^{3.5}$ K cm^{-3} (cf. Jenkins et al 1983; Reynolds 1993), and $\Sigma_{SFR} \sim 4 \times 10^{-3}$ M$_\odot$ yr^{-1} kpc^{-2} (McKee & Williams 1997 adjusted to our adopted IMF). Thus, Σ_{SFR} is roughly 7000 times greater in M 82 and the pressure is roughly 3000 times greater. This agrees with Lord et al (1996) who estimate that both the thermal pressure and FUV intensity in M 82 are three-to-four orders of magnitude higher than in the local ISM.

Let us for the moment then adopt the conjecture that $P \propto \Sigma_{SFR}$, and derive a relation between $\Sigma_{H\alpha}$, U, and n_e utilizing photoionization models. Suppose the gas in the DIM is illuminated by an isotropic ionizing radiation field. Then the one-sided incident ionizing flux Φ_{Lyc} is related to the observed area-averaged Hα surface brightness of the cloud by

$$\Phi_{Lyc} = 4\pi \frac{\Sigma_{H\alpha}}{h\nu} \frac{1}{f_{H\alpha}} \frac{A_{proj}}{A_{tot}} e_{H\alpha} \tag{1}$$

(Vogel et al. 1995) where $e_{H\alpha}$ is the ratio of the intrinsic (extinction-corrected) and observed Hα surface brightness and $f_{H\alpha}$ is the fraction of recombinations which produce Hα photons (=0.46 for T = 10^4 K and Case B recombination). The ratio of observed area to total area A_{proj}/A_{tot} is determined by the nebular geometry. It is 1/2 for a slab and 1/4 for a sphere. We use 1/3 to represent an average case. According to the definition of U, we can express $U = 4\Phi_{Lyc}/n_e c$, therefore

$$\Sigma_{H\alpha} = 5.9 \times 10^{-14} \left(\frac{n_e}{1 \text{ cm}^{-3}} \right) U \, e_{H\alpha}^{-1} \quad \text{ergs s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2} \tag{2}$$

To compare this to our data, we need to understand how n_e in the DIM is related to the mean star-formation-rate per unit area, as measured by Σ_e. Since photoionized gas is generically in thermal equlibrium at a temperature of roughly 10^4 K (e.g. Osterbrock 1989), relating n_e to Σ_e is equivalent to determing the constant of proportionality in the relation $P \propto \Sigma_{SFR}$. To do this, we will adopt a purely empirical approach for the moment and insist that this constant agree with values for P and Σ_{SFR} in the ISM of the Milky Way. Later we will explore the possible physical basis of this.

In the local disk of the Milky Way, $\Sigma_{SFR} \sim 4 \times 10^{-3}$ M$_\odot$ yr^{-1} kpc^{-2} implies an average intrinsic Hα surface brightness for the disk of 1.2×10^{-16} ergs s^{-1} cm^{-2} arcsec^{-2} (where we have assumed contnuous star-formation with a Salpeter IMF extending from 0.1 to 100 $M_\odot$ - Leitherer & Heckman 1995). A thermal pressure of $P/k \sim 10^{3.5}$ K cm^{-3} implies n$_e \sim 0.16$ cm^{-3} in the photoionized gas. Thus, the predicted relation between Σ_e and n_e based on our own Galaxy is:

$$\Sigma_e = 7.4 \times 10^{-16} \left(\frac{n_e}{1 \text{ cm}^{-3}} \right) e_{H\alpha}^{-1} \quad \text{ergs s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2} \tag{3}$$

Photoionization models of the DIM (Sokolowski 1993) are able to reproduce the observed emission-line ratios provided that the cosmically-abundant, refractory elements (i.e. Fe and Si) are largely locked-up in dust grains, as in the case of diffuse clouds in our own Galaxy (cf. Savage & Sembach 1996 and references therein). The models also better match the data if the radiation field incident on the DIM has been hardened due to radiative transfer en route to the DIM (e.g. there is an optical depth of-order unity at the Lyman edge between the DIM and the O stars). Adopting these 'depleted and hardened' models, we then estimate an empirical relation

$$\frac{[SII]\lambda\lambda 6716,6731}{H\alpha} = 1.1 \times 10^{-2}\ U^{-0.58} \tag{4}$$

appropriate for the range of the observed DIM lineratios ([SII]/H$\alpha \approx 0.3$ – 1.5). This enables us to relate [SII]/Hα approximately to $\Sigma_{H\alpha}/\Sigma_e$. The ratio of equations [2] and [3] imply that $\Sigma_{H\alpha}/\Sigma_e = 80$ U.

Thus, using Equation [4] above, we obtain:

$$\frac{[SII]\lambda\lambda 6716,6731}{H\alpha} = 0.14\ \left(\frac{\Sigma_{H\alpha}}{\Sigma_e}\right)^{-0.58} \tag{5}$$

This relation is represented by the solid line in Figure 2. The data agree reasonably well with the prediction in the faint gas (e.g. $\Sigma_{H\alpha}/\Sigma_e < 1$). The deviation of the data from the prediction at higher surface brightnesses ($\Sigma_{H\alpha}/\Sigma_e > 1$) will be briefly discussed in section 4.3 below.

As a 'sanity check' we now estimate the values of n_e in normal disks and starbursts that are implied by the measured values of Σ_e based on Eq. [3]. One should keep in mind that Σ_e may need to be corrected for inclination, so the values given here are upper limits, especially for the starburst sample where the inclination is high. We infer an average n_e of 0.4 $e_{H\alpha}$ cm^{-3} from the observed Σ_e for the normal galaxies. Taking a typical extinction of 1 magnitude for Hα (Kennicutt 1983) we obtain $n_e = 1.0$ cm^{-3}. This is several times larger than the value $n_e \sim 0.16$ cm^{-3} for the Reynolds layer (Reynolds 1993). There might be two major reasons for this discrepancy. Firstly, the Hα extinction in the DIM may be less than the typical HII region value of 1 magnitude. Secondly, simple considerations of hydrostatic equilibrium (see below) imply that the total ISM pressure (e.g. the sum of thermal, turbulent, cosmic ray, and magnetic pressures) decreases with galactocentric distance, so that the thermal pressure and hence electron density in the DIM may be higher in the inner regions of galaxies. Now, n_e for the Reynolds layer has been measured in the solar neighborhood (about 8 kpc from the Galactic center), while r_e in our normal galaxies is typically 2–4 kpc (see Table 2). The electron density for the DIM in starbursts

estimated from Σ_e averages ~ 24 cm^{-3}, after correcting for two magnitudes of extinction in Hα (Armus, Heckman, & Miley 1989). This value for n_e is then considerably higher than that in normal galaxies (as expected).

To summarize, we have shown that a model in which the DIM in both starburst and normal galaxies is photoionized gas whose thermal pressure is proportional to the mean rate of star-formation per unit area in the galaxy can quantitatively reproduce the observed unified correlation between the ionization state of the DIM ([SII]$\lambda\lambda$ 6716,6731/Hα line ratio) and the relative surface-brightness of the DIM shown in Figure 2. To make this test we have fixed the constant of proportionality in the relation $P \propto \Sigma_{SFR}$ to its value in the local disk of the Milky Way. We now turn to the possible physical basis of this relation.

4.2. A Supernova-Regulated ISM Pressure

Suppose we assume that the average thermal gas pressure P within r_e is maintained by the energy and mass released by supernovae (and stellar winds) inside r_e. We can then relate P and therefore n_e in the DIM to the effective surface brightness Σ_e.

Chevalier and Clegg (1985) have shown that for the case of spherical symmetry and adiabatic conditions

$$P = 0.12\ \dot{M}^{1/2}\ \dot{E}^{1/2}\ r_e^{-2} \tag{6}$$

Where $\dot{M}$ and $\dot{E}$ are the rates at which gas in the ISM is shocked and heated respectively. While this is exact for a spherically-symmetric case, its difference from a disk geometry can be shown to be negligible (provided that the gas is adiabatic - see below).

The starburst models of Leitherer & Heckman (1995) predict a simple scaling between the rate at which a starburst would return kinetic energy ($\dot{E}$) and ionizing photons (Q). Case B recombination gives the scaling from Q to the Hα luminosity. Now $\dot{M}$ is the amount of mass per unit time that is heated by supernovae and stellar winds. This will be larger than the ejecta directly returned from the massive stars by a 'mass-loading' factor m. For a standard Salpeter IMF extending up to 100 M$_\odot$ and a constant rate of star-formation for a time longer than 40 Myr, the Leitherer & Heckman models and equation 6 above then imply that n_e is related to Σ_e by

$$\Sigma_e \simeq 1.4 \times 10^{-15} \left(\frac{n_e}{1\ \mathrm{cm}^{-3}}\right)\ m^{-1/2}\ e_{H\alpha}^{-1} \qquad \mathrm{ergs\ s^{-1}\ cm^{-2}\ arcsec^{-2}} \tag{7}$$

where we have assumed $P/2n_ek = 10^4$ K. Eq. [7] agrees with the scaling relation between Σ_e and n_e (eq. [3]) of the local disk, for an appropriate m value (see below).

We can compare equation [6] to conditions in the local disk of our own Galaxy. Based on the rates at which stellar winds and supernovae inject mass and kinetic energy ($\sim 8\times10^{-4}$ M$\odot$ yr^{-1} kpc^{-2} and 1.2×10^{39} ergs s^{-1} kpc^{-2} respectively) within 3 kpc from the Sun (Abbott 1982; Jura & Kleinmann 1989), the predicted thermal pressure of the hot gas is $\sim$2200 m$^{1/2}$ K cm^{-3}, compared to the representative value of $10^{3.5}$ K cm^{-3} from observations of neutral (Jenkins et al. 1983) and ionized (Reynolds 1993) diffuse gas near the Galactic midplane. The required amount of mass heated per unit time is about twice as much as that injected directly by supernovae and stellar winds ($m \sim 2$). Only about 1/3 of this returned mass comes from high-mass stars (M$>$ 5 M$_\odot$),with the bulk coming from intermediate-mass AGB stars (Jura & Kleinmann 1989). The situation in starbursts–where the mass is returned almost entirely by high-mass stars (Leitherer & Heckman 1995)–is therefore somewhat different. Values for $m \sim 3$ to 10 have been estimated in starburst galaxies based on the mass, luminosity, and temperature of the X-ray emitting gas (e.g. Suchkov et al 1996; Della Ceca et al 1997; Wang et al 1997).

Equation [6] assumes that the thermal gas pressure is determined by the deposition of mass and energy by supernovae and stellar winds, that the hot gas that results permeates the region of star-formation, and that radiative losses are negligible. These assumptions may be valid in starbursts driving superwinds (cf. Heckman, Lehnert, & Armus 1993), but probably not in the ISM in normal galaxy disks where the interaction between stellar ejecta and the ISM is more complex (cf. Cioffi & Shull 1991). We therefore consider next a different physical interpretation of the relation between gas pressure and star-formation intensity.

4.3. Hydrostatic Equilibrium and Pressure-Regulated Star Formation

As discussed above, the results in Figure 2 can be understood if the DIM in both normal and starburst galaxies is photoionized, has a roughly constant characteristic density in each galaxy, and the characteristic thermal pressure in the DIM is proportional to the rate of star-formation per unit area in that galaxy. In section 4.2, we considered the possibility that the physical coupling was provided by the energy and mass deposited in the ISM by supernovae and massive stars. Here, we consider a different interpretation, namely that the total pressure in the ISM is specified by hydrostatic equilibrium (e.g. Boulares & Cox 1990), and that the star-formation rate per unit area is related to, or perhaps limited by, this pressure (cf. Dopita 1985).

In a case of simple hydrostatic equilibrium, the total (thermal, turbulent, cosmic ray,

plus magnetic) mid-plane pressure in a disk galaxy is given by

$$P_{tot} \propto \Sigma_{gas}(\Sigma_* + \Sigma_{gas}) \propto \Sigma_{gas}\Sigma_{tot} \tag{8}$$

On empirical grounds, it is well-established that the star-formation-rate per unit area (Σ_{SFR}) in disk galaxies scales with both Σ_{gas} and Σ_{tot}. This suggests that there might be a simple, direct scaling between Σ_{SFR} and P_{tot}. In fact, Dopita & Ryder (1994) parameterize the problem as

$$\Sigma_{SFR} \propto \Sigma_{gas}^m \Sigma_{tot}^n \tag{9}$$

and find empirically that $m + n = 2.0 \pm 0.5$. Kennicutt (1998) finds that $\Sigma_{SFR} \propto \Sigma_{gas}^{1.4}$, while Figure 1 in Dopita & Ryder (1994) implies $\Sigma_{SFR} \propto \Sigma_*^{0.6}$. Except in the most extreme starbursts, it is reasonable to take $\Sigma_{tot} \gg \Sigma_{gas}$, so that this last result means roughly that $\Sigma_{SFR} \propto \Sigma_{tot}^{0.6}$. Combining these results suggests that:

$$\Sigma_{SFR} \propto \Sigma_{gas}^{1.4}\Sigma_{tot}^{0.6} \propto P_{tot}(\Sigma_{gas}/\Sigma_{tot})^{0.4} \tag{10}$$

Since there is only a small observed variation in $\Sigma_{gas}/\Sigma_{tot}$ (factors of a few) in the disks of late-type galaxies and typical starbursts, this implies that there should be a proportionality between P_{tot} and Σ_{SFR}. If we now assume that the thermal component of the pressure scales with the total pressure, this is just what we require in order to understand Figure 2.

As we emphasized in section 4.1 above, the rough quantitative agreement between photoionization models and the properties of the DIM in the starbursts and normal galaxies is independent of the nature of the physical, causal connection between the thermal pressure in the DIM and Σ_{SFR}. The agreement shown in Figure 2 is based simply on requiring that the constant of proportionality between these two quantities is consistent with values in the local disk of our Galaxy.

4.4. The High Surface-Brightness Gas

While the model of a photoionized, roughly isobaric DIM provides a satisfactory quantitative match to the data on the low surface brightness gas ($\Sigma_{H\alpha}/\Sigma_e < 1$), Figure 2 shows that there is a systematic offset between the predictions and the data in the high surface brightness range ($\Sigma_{H\alpha}/\Sigma_e \sim 1$ – 10). This disagreement is in the sense that the observed emission-line ratio [SII]/Hα is too high, and therefore that the actual ionization parameter U in the gas must be smaller than predicted. This could be explained if the density in the high-surface-brightness gas is higher than estimated in the model. This

is entirely plausible, since the high surface-brightness gas (the HII regions) will likely be significantly over-pressured with respect to the surrounding diffuse ISM (e.g. the HII regions may be self-gravitating or expanding into the lower-pressure DIM). More quantitatively, we note that the offset between the model and data for log([SII]/Hα) in the bright gas (a difference of ~ 0.6 dex on average) would translate into a difference of a factor of $\sim$10 lower U and hence higher n_e.

An additional factor is that the Sokolowski models we have utilized for the DIM: 1) adopted a dust-depleted abundance pattern and 2) assumed that the ionizing radiation field had been hardened as it propagated to the DIM. Partial depletion onto grains may occur in HII regions (cf. Garnett et al 1995), but the assumption of spectral hardening is not appropriate for the HII regions. Dropping these assumptions would decrease the predicted ratio of [SII]/Hα for a given U, and make the discrepancy worse in Figure 2. This would require a decrease in U (and increase in n_e) by an additional factor of ~ 3.

Using the value for n_e in the DIM in normal galaxies estimated from Σ_e above, we would then require a density of $\sim$30 cm^{-3} in the HII regions. This agrees reasonably well with the average values of n_e in disk HII regions of $\sim$10–100 cm^{-3} (e.g. O'Dell and Castañeda 1984; Kennicutt, Keel & Blaha 1989) measured with the [SII] and [OII] doublets. Our measurements of [SII]λ6716/[SII]λ6731 for bright HII regions suggest similar values for n_e.

Following the same reasoning, we would estimate that the required density in the high-surface brightness gas in the centers of the starbursts must also be about 30 times higher than in the low-surface-brightness gas: $n_e \sim 700\ cm^{-3}$. This is in satisfactory agreement with the directly measured central densities of 300 to 1000 cm^{-3} (e.g. Heckman, Armus and Miley 1990; Lehnert and Heckman 1996a).

5. CONCLUSIONS

We have compared the emission-line properties of the low surface brightness gas in starburst galaxies with the DIM in normal spirals. Both samples show similar attributes of enhanced low-ionization forbidden-line strengths (as represented by [SII]/Hα) relative to typical HII region values and a strong inverse correlation between Hα surface-brightness and the [SII]/Hα line ratio (in the form of a smooth transition from high surface brightness to low surface brightness regions). The gas kinematics show no strong correlation with surface brightness and line ratio in the combined samples.

Although the Hα surface brightness corresponding to a given [SII]/Hα line ratio is

preferentially about an order-of-magnitude larger in starbursts than in normal galaxies, we have demonstrated that this can be understood as a consequence of the proportionately higher mean Hα surface brightnesses of the starbursts. That is, we have shown that the *relative* surface brightness at a particular location, defined as the absolute surface brightness there ($\Sigma_{H\alpha}$) scaled by the mean surface brightness within the Hα half-light radius (Σ_e) for the galaxy as-a-whole, exhibits a remarkably universal correlation with the [SII]/Hα line ratio for normal and starburst galaxies alike. This suggests that the emission-line properties of the low surface brightness gas in both groups of galaxies can be unified to a simple relation between line ratio and relative surface brightness, and that the variations in line ratio and relative surface-brightness are controlled by a single parameter.

We have constructed a simple photoionization model to explain the correlation between $\Sigma_{H\alpha}/\Sigma_e$ and line ratio. We have pointed out that the [SII]/Hα line ratio has an inverse dependence on the ionization parameter U (the local ratio of ionizing photons and electrons in the photoionized gas). For simple recombination, $\Sigma_{H\alpha}$ is proportional to the local intensity of the ionizing radiation field. *If* the average thermal pressure in the diffuse ISM in a galaxy (P) is proportional to the average rate of star-formation per unit area (Σ_{SFR}), then since Σ_{SFR} can be measured by Σ_e, it follows that $U \propto \Sigma_{H\alpha}/\Sigma_e$. We have argued that this result naturally explains the universal dependence of line ratios on relative surface brightness.

Our simple model is able to quantitatively reproduce the data for normal and starburst galaxies provided that the constant of proportionality in the relation between P and Σ_{SFR} is consistent with the observed values for both quantities in local Galactic ISM. Thus, we have emphasized that the agreement between our simple photoionization model and the data is independent of the detailed physical connection between star formation and ISM pressure.

We have discussed two ways in which P might be physically related to Σ_{SFR}. Following Chevalier & Clegg (1985) we have first assumed that P is regulated by the feedback of mass and energy from supernovae and massive stars. Scaling the amount of mass heated per supernova so that the predicted thermal pressure matches the observed pressure in the local Milky Way disk, we found that the photoionization model agrees roughly with the DIM data in both starburst and normal galaxies. As an alternative, we explored the possibility (e.g. Dopita 1985) that Σ_{SFR} is determined (or limited) by the total (thermal, turbulent, cosmic ray, plus magnetic) pressure P_{tot}, and that P_{tot} and P are determined by a simple hydrostatic equilibrium condition in galactic disks, i.e. $P \propto P_{tot} \propto \Sigma_{tot}\Sigma_{gas}$. We used recent empirical results from Kennicutt (1998) and Dopita & Ryder (1994) to argue that $\Sigma_{SFR} \propto P f_{gas}^{0.4}$, where f_{gas} is the fractional gas mass in the disk. Since f_{gas} varies only

by small factors, this means that Σ_{SFR} does roughly scale with P.

The simple model can not account for the emission-line ratios in the high surface-brightness gas (the giant HII regions) unless the densities and thermal pressures there are roughly 30 times larger than in the DIM. We argue that this is both reasonable physically and in agreement with measurements.

We conclude that the low surface brightness gas in the starbursts shares a common nature with the DIM in the normal galaxies, and propose that the former can be regarded as the same gas phase as the latter. Further morphological observations of the low surface brightness gas in starbursts can confirm this suggestion.

We thank S. Baum, D. Calzetti, R. Kennicutt, R. Wyse, C. Norman, C. Martin, and A. Ferguson for useful discussions and an anonymous referee for constructive suggestions.

Fig. 1.— The [SII]$\lambda\lambda$6717,6731/Hα line ratio vs. the Hα surface brightness at the same position in the galaxy. The starburst data are represented by small triangles and include 32 galaxies for which photometric measurements are available (Lehnert & Heckman 1995). These data cover the regions from starburst nuclei to their outer disks. The data for normal galaxies are represented by different symbols as follows. Stars—M 101, triangles—M 51, solid circles—M 81, crosses—NGC 4395, open circles—NGC 2403, diamonds—NGC 6946, 'I'—IC 342. These data are from the DIM, bright HII regions, and intermediate regions around isolated HII regions. The DIM points lie to the upper left, the HII regions to the lower right, and the intermediate points lie in between.

Fig. 2.— The [SII]$\lambda\lambda$6717,6731/Hα line ratio vs. the relative Hα surface brightness $\Sigma_{H\alpha}/\Sigma_e$ where Σ_e is the mean surface brightness within the Hα half-light radius r_e. Symbols are the same as Figure 1. The data includes only 19 starburst galaxies (in the Lehnert & Heckman 1995 sample) that have measured values for Σ_e. Regions beyond $2r_e$ are excluded because the measurement errors are large and shock-heating by superwinds may be significant in these outer regions. This figure demonstrates the universal relation between line-ratio and relative surface brightness of the diffuse emission-line gas for galaxies with different SFRs. The solid line is the prediction from a simple photoionization model for the DIM assuming the thermal pressure in the diffuse gas is related to the star-formation rate per unit area (see text for details). The assumptions in the photoionization models are not appropriate for the high-surface-brightness gas—the HII regions with $\Sigma_{H\alpha}/\Sigma_e > 1$.

[a]Integrated Hα luminosity corrected for foreground Galactic extinction. Data are from Hα + [NII] luminosities listed by Lehnert & Heckman (1995) and have been corrected to pure Hα luminosities based on average [NII]/Hα ratios within 2 half-light radii.

[b]Half-light radius in Hα measured at an inner circle in the images that enclosed one-half of the total Hα light from the galaxy (Lehnert & Heckman 1995).

[c]Distances adopted from Lehnert & Heckman 1995.

[d]Mean Hα surface brightness within half-light radius r_e derived from $L_{H\alpha}$ (Col. 2) and r_e (Col. 3). The values have been corrected for foreground Galactic extinction. The values can be converted to emission measure based on the relation that 5×10^{-17} erg s^{-1} cm^{-2} $arcsec^{-2}$ corresponds to 25 pc cm^{-6}, assuming an electron temperature of 10^4 K.
